Abstract—This paper considers the problem of shooter localization using a network of soldier-worn gunfire detection systems. Proposed scheme utilizes the benefits of sensor network layout of all the sensors within a small combat unit to help refine localization accuracy. If the soldier is within the field of view of the shockwave, then using the acoustic phenomena analysis of small-arms fire, the gunfire detection system can localize the source of the incoming fire and the bullet’s trajectory with respect to the sensor location. These individual solutions, usually in the form of bearing and range relative to the soldier, are then relayed to the central node. At the central node level, the individual solutions are fused along with the GPS locations on the soldiers to yield a highly accurate geo-rectified solution.

Keywords: Shooter localization, gunfire detection system, maximum likelihood estimation, Gauss-Newton method.

I. INTRODUCTION

There is an eminent need for highly accurate small-arms gunfire detection systems on individual soldiers for added battlefield situational awareness and threat assessment. Today, several acoustic shooter localization systems are commercially available [1], [2]; an overview of such systems can be found in [3]. Currently operational Soldier Wearable Gunfire Detection Systems (SW-GDSs) can provide an appropriate level of localization accuracy as long as the soldier is at an ideal location (range, attitude, etc.) when incoming fire is received [4]–[6]. The localization system suffers severe performance degradation when the soldier is at a non-ideal location. Moreover, when a relative solution, i.e., the shooter location relative to the sensor, is transformed into a geo-rectified solution using a magnetometer and GPS, the solution often becomes unusable due to localization errors. Geo-rectified solutions are necessary when displaying hostile fire icons on a Command and Control Geographic Information System (C2 GIS) map display.

SW-GDSs use acoustic phenomena analysis of small-arms fire to localize the source of incoming fire, usually with a bearing and range relative to the user [7]. These individual SW-GDSs operate separately and are not designed to exploit the sensor network layout of all the soldiers within a Small Combat Unit (SCU) to help increase accuracy. Researchers are exploring some novel solutions that utilize the team aspect of these SCUs by exploiting all SW-GDSs in a squad/platoon to increase detection rates and accuracy [8]–[10]. This paper presents the development of a sensor fusion module that would take full advantage of the team aspect of a SCU to provide a fused solution that would be highly accurate and suitable for a C2 GIS map display compared to the individual soldier’s solution. The objective here is to improve accuracy across an entire SCU so even soldiers in non-ideal settings (out of range, bad angle, etc.) can exploit the good solutions from their neighbors to come up with improved solutions: both geo-rectified and relative.

The individual SW-GDSs considered here is composed of a passive array of microphones that is able to localize a gunfire event by measuring the direction of arrival for both the acoustic wave generated by the muzzle blast and the shockwave generated by the supersonic bullet [1], [2]. After detecting a gunfire, the individual sensors report their solution along with their GPS positions to a central node. At the central node, the individual solutions are fused along with the GPS positions to yield an highly accurate, geo-rectified solution, which is then relayed back to individual soldiers for added situational awareness. Structure of this paper is as follows: section II presents the measurement model for the acoustic sensor nodes, and section III presents the localization algorithm that converts the sensor measurements to a gunfire position estimate. Details of the central node data fusion and the corresponding nonlinear least-squares problem is given in section IV. Section V presents the Gauss-Newton method to solve the nonlinear least-squares problem and section VI presents the results from numerical simulations. Finally, section VII concludes the paper and discusses the current research challenges.

II. PROBLEM SETUP

Consider a SCU consist of $n$ individual soldiers equipped with the SW-GDS. In order to set up the problem and develop a sensor model, we first consider a scenario where there is only one shooter and the SW-GDS receives both the muzzle blast and the shockwave. The shooter or the target location and the soldier or the $i^{th}$ sensor location are defined as $T$ and $S_i$, respectively. For simplicity, the problem is formulated in $\mathbb{R}^2$, i.e., $T \in \mathbb{R}^2 \equiv \begin{bmatrix} x_T \\ y_T \end{bmatrix}$ and $S_i \in \mathbb{R}^2 \equiv \begin{bmatrix} x_{S_i} \\ y_{S_i} \end{bmatrix}$. Now define the individual range, $r_i$, and bearing, $\phi_i$, between the $i^{th}$ sensor node and the target as

$$r_i = \sqrt{(T_x - S_{ix})^2 + (T_y - S_{iy})^2}$$ (1)

$$\phi_i = \arctan2 \left( \frac{T_y - S_{iy}}{T_x - S_{ix}} \right)$$ (2)
When a gun fires, the blast from the muzzle produces a spherical acoustic wave that can be heard in any direction. The bullet travels at supersonic speeds and produces an acoustic shockwave that emanates as a cone from the trajectory of the bullet. Because the bullet is traveling faster than the speed of sound, the shockwave arrives at the sensor node before the wave from the muzzle blast, which we simply refer to as the muzzle blast. Figure 1 illustrates the geometry of the shockwave and the muzzle blast for the $i$th sensor node when the orientation of the bullet trajectory is $\omega$ with respect to the horizontal axis. As the bullet pushes air, it creates an impulse wave. The wavefront is a cone whose angle $\theta$ with respect to the trajectory is

$$\theta = \arcsin \left( \frac{1}{m} \right) \quad (3)$$

where $m$ is the Mach number. The Mach number is assumed to be known since the typical value for a Mach number is $m = 2$ [7]. Since the Mach number directly influences the range estimates, uncertainty in bullet speed may be treated as range estimation error. As indicated in figure 1, the angle $\phi_i$ indicates the direction of arrival (DOA) of the muzzle blast, and $\phi_i$ indicates the DOA of the shockwave. The muzzle blast DOA is measured counter-clockwise such that $0 \leq \phi_i \leq 2\pi$. For a more detailed description of the scenario, please refer to [7]. Figure 2 indicates the field of view (FOV) for both the muzzle blast and the shockwave. Note that the FOV of the muzzle blast is $2\pi$, i.e., omnidirectional, and the FOV for the shockwave is $\pi - 2\theta$. SW-GDS receives the shockwave only if the muzzle blast DOA is within the bounds

$$\pi/2 + \theta + \omega < \phi_i < 3\pi/2 - \theta + \omega \quad (4)$$

Now the DOA angle for the shockwave can be written as

$$\varphi_i = \begin{cases} -\frac{\pi}{2} - \theta + \omega, & \text{if } \pi + \omega < \phi_i < \frac{3\pi}{2} - \theta + \omega; \\ \frac{\pi}{2} + \theta + \omega, & \text{if } \frac{\pi}{2} + \theta + \omega < \phi_i < \pi + \omega. \end{cases} \quad (5)$$

The first case $\pi + \omega < \phi_i < \frac{3\pi}{2} - \theta + \omega$ corresponds to the scenario where the sensor is located above the bullet trajectory and the third case $\frac{\pi}{2} + \theta + \omega < \phi_i < \pi + \omega$ corresponds to the scenario where the sensor is located below the bullet trajectory (as shown in figure 1). The case where $\phi_i = \pi + \omega$ corresponds to the scenario when the sensor is located on the bullet trajectory and here we do not consider such a scenario.

If $\phi_i$ is outside the bound given in (4), the sensor node only receives the muzzle blast and it is outside the FOV of the shockwave. Under the assumptions that the bullet maintains a constant velocity over its trajectory, the time difference between the shockwave and the muzzle blast can be written as [2]

$$\tau_i = \frac{r_i}{c} \left[ 1 - \cos |\phi_i - \varphi_i| \right], \quad \forall \phi_i \neq \varphi_i \quad (6)$$

where $c$ indicates the speed of sound. Utilizing (5), the bullet trajectory angle, $\omega$, can be obtained from the shockwave DOA angle. Though this paper assumes that the bullet speed is constant over its trajectory, others have proposed localization algorithms [10], [11] that employ more realistic bullet speed models at the expense of computational efficiency.

III. DATA FUSION AT SENSOR NODE LEVEL

When the sensor node is within the FOV of the shockwave, the three available measurements are the two DOA angles and the time difference of arrival (TDOA) between the muzzle blast and the shockwave, i.e.,

$$\hat{\phi}_i = h_1(T, S, \omega) + \eta_\phi \quad (7)$$

$$\hat{\varphi}_i = h_2(T, S, \omega) + \eta_\varphi \quad (8)$$

$$\hat{\tau}_i = h_3(T, S, \omega) + \eta_\tau \quad (9)$$

where $h_1(\cdot)$ is given in (2), $h_2(\cdot)$ is given in (5), and $h_3(\cdot)$ is given in (6). The measurement noise is assumed to be zero mean Gaussian white noise, i.e., $\eta_\phi \sim N(0, \sigma_\phi^2)$, $\eta_\varphi \sim N(0, \sigma_\varphi^2)$ and $\eta_\tau \sim N(0, \sigma_\tau^2)$. Let $\hat{T}_i = [\hat{\phi}_i \ \hat{\varphi}_i \ \hat{\tau}_i]$ denotes the individual sensor level estimates on the target bearing, range, and the bullet trajectory. Data fusion at the sensor node involves calculating these individual estimates based on the three sensor measurements.

Using (5), the bullet trajectory angle, $\omega$, can be obtained from the shockwave DOA measurements. Thus, the observations on the trajectory angle can be written as

$$\hat{\omega}_i = \omega_i + \eta_\omega \quad (10)$$
Now the likelihood function, \( p(\hat{\omega}_i|T, S_i, \omega) \), can be written as
\[
p(\hat{\omega}_i|T, S_i, \omega) = N(\omega, \sigma_\omega^2)
\]
From (6), the range can be written in terms of the TDOA as
\[
r_i = \frac{c r_i}{1 - \cos|\phi_i - \varphi_i|}
\]
(11)
The observation of \( r_i \) may be written as
\[
\hat{r}_i = \frac{c r_i}{1 - \cos|\phi_i - \varphi_i|}
\]
(12)
Using the first-order Taylor series, the range measurement can be approximated as
\[
\hat{r}_i \approx \frac{c r_i}{1 - \cos|\phi_i - \varphi_i|} + \left[ \frac{c r_i \sin|\phi_i - \varphi_i|}{1 - \cos|\phi_i - \varphi_i|^2} \right] \eta r
\]
\[
= r_i + H(T, S_i, \omega) \eta r
\]
where
\[
\eta r = \left[ \eta_T \eta_{\varphi r} \right] \& \eta_{\varphi \varphi} \sim N(0, \sigma_\omega^2 + \sigma_r^2)
\]
and
\[
H(T, S_i, \omega) = \left[ \frac{c r_i \sin|\phi_i - \varphi_i|}{1 - \cos|\phi_i - \varphi_i|^2} \right]
\]
Now the likelihood \( p(\hat{r}_i|T, S_i, \omega) \) can be approximated as
\[
p(\hat{r}_i|T, S_i, \omega) \approx N(r_i, \sigma_r^2(T, S_i, \omega))
\]
where the variance \( \sigma_r^2(T, S_i, \omega) \) can be written as
\[
\sigma_r^2(T, S_i, \omega) = H(T, S_i, \omega) \begin{bmatrix} \sigma_T^2 & 0 \\ 0 & \sigma_\omega^2 + \sigma_r^2 \end{bmatrix} H^T(T, S_i, \omega)
\]
(13)
Thus, the likelihood function \( p(T_i|T, S_i, \omega) \) can be approximated as
\[
p(T_i|T, S_i, \omega) \approx N(\mu_{T_i}, \Sigma_{T_i})
\]
(14)
where
\[
\mu_{T_i} = \begin{bmatrix} \phi_i \\ r_i \\ \omega \end{bmatrix} \& \Sigma_{T_i} = \begin{bmatrix} \sigma_\phi^2 & 0 & 0 \\ 0 & \sigma_r^2(T, S_i, \omega) & 0 \\ 0 & 0 & \sigma_\omega^2 \end{bmatrix}
\]
It is assumed that a GPS receiver is used to obtain an accurate positioning on each sensor. Thus, the position observation on the sensors are given as
\[
\tilde{S}_i = \begin{bmatrix} S_{ix} \\ S_{iy} \end{bmatrix} + \begin{bmatrix} v_{ix} \\ v_{iy} \end{bmatrix}
\]
(15)
where the noise terms are assumed to be zero mean Gaussian white, i.e., \( v_{ix} \sim N(0, \sigma_v^2) \) and \( v_{iy} \sim N(0, \sigma_v^2) \). Now the GPS measurement likelihood function may be written as
\[
p(\tilde{S}_i|S_i) \sim N(\begin{bmatrix} S_{ix} \\ S_{iy} \end{bmatrix}, \begin{bmatrix} \sigma_v^2 & 0 \\ 0 & \sigma_v^2 \end{bmatrix}) \equiv N(\mu_{S_i}, \Sigma_{S_i})
\]
(16)

**Assumption 1.** Without loss of generality, it can be assumed that the GPS observations on sensor position are independent of target location, observations on target location, and the projectile trajectory information, i.e.,
\[
p(\tilde{S}_i|S_i) = p(\tilde{S}_i|T, S_i, \omega) = p(\tilde{S}_i|T_i, T, S_i, \omega)
\]
Base on assumption 1, the joint probability \( p(T_i, \tilde{S}_i|T, S_i, \omega) \) can be calculated as
\[
p(T_i, \tilde{S}_i|T, S_i, \omega) = p(\tilde{S}_i|T_i, T, S_i, \omega) p(T_i|T, S_i, \omega)
\]
(17)
Substituting (14) and (16), the above joint likelihood can be written as
\[
p(T_i, \tilde{S}_i|T, S_i, \omega) \approx N(\mu_{S_i}, \Sigma_{S_i}) N(\mu_{T_i}, \Sigma_{T_i})
\]
Now using the Bayes’ rule, the node level estimates are given as
\[
p(T, S_i, \omega|\tilde{T}_i, \tilde{S}_i) = \int \int p(T_i, \tilde{S}_i|T, S_i, \omega) p(T, S_i, \omega) dT dS_i d\omega
\]
(19)
Note that the denominator in (19) indicates the normalization factor and since no a priori information is assumed to be known, a uniform pdf may be selected for \( p(T, S_i, \omega) \). Since the denominator is the normalizing term, which is a constant with respect to \( T, S_i \), and \( \omega \), equation (19) can be written as
\[
p(T, S_i, \omega|\tilde{T}_i, \tilde{S}_i) \approx \alpha p(\tilde{T}_i, \tilde{S}_i|T, S_i, \omega)
\]
(20)
where \( \alpha \) is a constant.

Now for a sensor located in the FOV of the shockwave, the target location can be estimated as:
\[
\hat{T}_x = \hat{S}_{ix} + \hat{r}_i \cos(\hat{\varphi}_i)
\]
(21)
\[
\hat{T}_y = \hat{S}_{iy} + \hat{r}_i \sin(\hat{\varphi}_i)
\]
(22)
When the sensor is located outside the shockwave FOV, the only estimate would be the bearing angle. After individual estimates are obtained at the sensor node level, the measured information is transmitted to a central node where it is fused to obtain a more accurate estimate of the shooter location.

**IV. Data Fusion at the Central Node**

While sensors in the FOV of the muzzle blast and the shockwave yield a range, bearing, and trajectory angle estimates, the gunfire detection systems outside the FOV of the shockwave yield a muzzle blast DOA. Also, GPS measurements are available on each sensor locations. At the central node, this information from the individual sensor nodes is fused to obtain an accurate estimate of the shooter location, bullet trajectory angle, and the sensor location.
Based on assumption 1, the joint likelihood function associated with each sensor, i.e., $p\left(\hat{T}_i, \hat{S}_i|T, S_i, \omega\right)$, can be written as
\[
p\left(\hat{T}_1, \hat{S}_1|T, S_1, \omega\right) = p\left(\hat{S}_1|\hat{T}_1, T, S_1, \omega\right) \cdot p\left(\hat{T}_1|T, S_1, \omega\right)
\]
Let $S_{1:n} = \{S_1, S_2, \ldots, S_n\}$, $\hat{T}_{1:n} = \{\hat{T}_1, \hat{T}_2, \ldots, \hat{T}_n\}$, and $\hat{S}_{1:n} = \{\hat{S}_1, \hat{S}_2, \ldots, \hat{S}_n\}$, where $n$ indicates the number of sensors. Since the sensor nodes are independent of each other, the joint conditional density $p\left(\hat{T}_{1:n}, \hat{S}_{1:n}|T, S_{1:n}, \omega\right)$ can be defined as
\[
p\left(\hat{T}_{1:n}, \hat{S}_{1:n}|T, S_{1:n}, \omega\right) = \prod_{i=1}^{n} p\left(\hat{T}_i, \hat{S}_i|T, S_i, \omega\right)
\]
Here we consider the maximum likelihood approach to obtain the fused estimates. In the maximum likelihood estimation approach considered here, an estimate of the sensor locations, the shooter location, and the bullet trajectory angle are obtained so that the joint log-likelihood function is maximized, i.e.,
\[
\max_{T, S_{1:n}, \omega} \ln \left\{ p\left(\hat{T}_{1:n}, \hat{S}_{1:n}|T, S_{1:n}, \omega\right) \right\} = \max_{T, S_{1:n}, \omega} \sum_{i=1}^{n} \ln \left\{ p\left(\hat{T}_i, \hat{S}_i|T, S_i, \omega\right) \right\}
\]
Based on the results given in the previous section, the criteria for the maximum likelihood estimation can be written as
\[
\max_{T, S_{1:n}, \omega} \sum_{i=1}^{n} \left\{ \ln \{\mathcal{N}(\mu_{T_i}, \Sigma_{T_i})\} + \ln \{\mathcal{N}(\mu_{S_i}, \Sigma_{S_i})\} \right\}
\]
Note that the densities $\mathcal{N}(\mu_{T_i}, \Sigma_{T_i})$ and $\mathcal{N}(\mu_{S_i}, \Sigma_{S_i})$ may be written as
\[
\mathcal{N}(\mu_{T_i}, \Sigma_{T_i}) = \frac{1}{\sqrt{2\pi\Sigma_{T_i}}} \exp \left\{ -\frac{1}{2} \left(\hat{T}_i - \mu_{T_i}\right)^T \Sigma_{T_i}^{-1} \left(\hat{T}_i - \mu_{T_i}\right) \right\}
\]
where
\[
\mu_{T_i} = \begin{bmatrix} \phi_i \\ r_i \\ \omega \end{bmatrix}, \quad \Sigma_{T_i} = \begin{bmatrix} \sigma_\phi^2 & 0 & 0 \\ 0 & \sigma_r^2(T, S_i, \omega) & 0 \\ 0 & 0 & \sigma_\omega^2 \end{bmatrix}
\]
and
\[
\mathcal{N}(\mu_{S_i}, \Sigma_{S_i}) = \frac{1}{\sqrt{2\pi\Sigma_{S_i}}} \exp \left\{ -\frac{1}{2} \left(\hat{S}_i - \mu_{S_i}\right)^T \Sigma_{S_i}^{-1} \left(\hat{S}_i - \mu_{S_i}\right) \right\}
\]
where
\[
\mu_{S_i} = \begin{bmatrix} S_i \\ S_y \end{bmatrix}, \quad \Sigma_{S_i} = \begin{bmatrix} \sigma_{S_i}^2 & 0 \\ 0 & \sigma_y^2 \end{bmatrix}
\]
After substituting (26) and (27) into (25), the maximum likelihood criteria may be written as
\[
\min_{T, S_{1:n}, \omega} \sum_{i=1}^{n} \left\{ \ln \left[ \frac{1}{\sqrt{2\pi\Sigma_{T_i}}} \exp \left\{ -\frac{1}{2} \left(\hat{T}_i - \mu_{T_i}\right)^T \Sigma_{T_i}^{-1} \left(\hat{T}_i - \mu_{T_i}\right) \right\} \right] + \ln \left[ \frac{1}{\sqrt{2\pi\Sigma_{S_i}}} \exp \left\{ -\frac{1}{2} \left(\hat{S}_i - \mu_{S_i}\right)^T \Sigma_{S_i}^{-1} \left(\hat{S}_i - \mu_{S_i}\right) \right\} \right] \right\} \]
Note that the term, $\ln \left[ \frac{1}{\sqrt{2\pi\Sigma_{S_i}}} \right]$, in above equation is present due to the fact that $\Sigma_{S_i}$ is a function of $T, S_i, \omega$. The last term, $\ln \left[ \frac{1}{\sqrt{2\pi\Sigma_{S_i}}} \right]$ can be ignored since $\Sigma_{S_i}$ is a known constant matrix. Since $\Sigma_{T_i}$ is assumed to be a diagonal matrix, (28) can be rewritten as
\[
\min_{T, S_{1:n}, \omega} \sum_{i=1}^{n} \left\{ \ln \left(\epsilon \sigma_r\right) + \frac{1}{2} \left(\hat{T}_i - \mu_{T_i}\right)^T \Sigma_{T_i}^{-1} \left(\hat{T}_i - \mu_{T_i}\right) + \frac{1}{2} \left(\hat{S}_i - \mu_{S_i}\right)^T \Sigma_{S_i}^{-1} \left(\hat{S}_i - \mu_{S_i}\right) \right\}
\]
where $\varepsilon$ is defined as
\[
\varepsilon = (2\pi)^{3/2} \sigma_\phi \sigma_\omega
\]
Apart from the initial term, $\ln(\varepsilon \sigma_r)$, the optimization problem given in (29) is similar to that used in the weighted nonlinear least-squares. Thus, the maximum likelihood approach presented here is similar to the weighted nonlinear least-squares estimation.

V. NONLINEAR LEAST SQUARES

There exist no closed form solution to the nonlinear least-squares optimization problem given in (29) and therefore a numerical approach needs to be used. A few common approaches to solving the nonlinear least-squares problem include the Gauss-Newton method, Nelder-Mead simplex method, and Marquardt method [12]. Almost all these approaches are iterative methods that require an initial approximation to the unknown parameters and provide successively better approximations. The iterative process is repeated until the parameters do not change to within specified limits.

This section provides the Gauss-Newton method for solving the nonlinear least squares problem given in (29). The main advantage of the Gauss-Newton method is that it exhibits a “quadratic convergence,” which, simply put, means that the uncertainty in the parameters after $p + 1$ iterations is proportional to the square of the uncertainty after $p$ iterations. Once these uncertainties begin to get small, they decrease quite rapidly. An additional advantage of the Gauss-Newton method is that it only requires calculating the first-order derivatives. The major problem with the Gauss-Newton method is that it sometimes diverges if the initial approximation is too far from truth.
In order to simplify the formulation, we treat $\Sigma_Ti$ as a known constant matrix. Thus, (29) can be rewritten as

$$
\min_{T, S_{i,\omega}} J = \frac{1}{2} \triangle y^T W \triangle y
$$

where

$$
\triangle y = \begin{bmatrix}
\tilde{T}_1 - \mu_{T_1} \\
\tilde{S}_1 - \mu_{S_1} \\
\vdots \\
\tilde{T}_n - \mu_{T_n} \\
\tilde{S}_n - \mu_{S_n}
\end{bmatrix}, W = \begin{bmatrix}
\Sigma_{T_1}^{-1} & 0 & 0 & 0 & 0 \\
0 & \Sigma_{S_1}^{-1} & 0 & 0 & 0 \\
0 & 0 & \ddots & 0 & 0 \\
0 & 0 & 0 & \Sigma_{T_n}^{-1} & 0 \\
0 & 0 & 0 & 0 & \Sigma_{S_n}^{-1}
\end{bmatrix}
$$

Let $x = [T_x \ T_y \ \omega \ S_{1x} \ S_{1y} \ \ldots \ S_{nx} \ S_{ny}]^T$ denote the parameters to be estimated and let $y = [f_1^T(x) \ \ldots \ f_i^T(x) \ \ldots \ f_n^T(x)]^T$ denote the measurement estimates. Here $f_i(x) = [\phi_i, r_i, \omega, S_{ix}, S_{iy}]^T$ is defined as

$$
f_i(x) = \begin{bmatrix}
\arctan \left( \frac{2 (T_y - S_{iy} - T_x - S_{ix})}{\sqrt{(T_x - S_{ix})^2 + (T_y - S_{iy})^2}} \right) \\
\omega \\
S_{ix} \\
S_{iy}
\end{bmatrix}
$$

(31)

Also let $\tilde{y}_i = [\tilde{y}_1^T, \ldots, \tilde{y}_i^T, \ldots, \tilde{y}_n^T]^T$ where $\tilde{y}_i = [\tilde{T}_i^T \ \tilde{S}_i^T]^T$. Now $\triangle y$ is defined as

$$
\triangle y = \tilde{y} - y
$$

Let the current estimates of $x$ be denoted as

$$
x^c = [T_x^c \ T_y^c \ \omega^c \ S_{1x}^c \ S_{1y}^c \ \ldots \ S_{nx}^c \ S_{ny}^c]^T
$$

Define

$$
\triangle x = x - x^c
$$

If the components of $\triangle x$ are sufficiently small, then using the first-order Taylor series approximation, we have

$$
f(x) \approx f(x^c) + F \triangle x
$$

(32)

where

$$
F = \left. \frac{\partial f}{\partial x} \right|_{x=x^c}
$$

Now the measurement residual $\triangle y$ can be linearly approximated as

$$
\triangle y \approx \tilde{y} - f(x^c) - F \triangle x = \triangle y^c - F \triangle x
$$

(33)

where $\triangle y^c = \tilde{y} - f(x^c)$. Substituting (33) in (30) yields

$$
J \approx \frac{1}{2} (\triangle y^c - F \triangle x)^T W (\triangle y^c - F \triangle x)
$$

(34)

The $\triangle x$ that minimizes the above cost function can be written as

$$
\triangle x = (F^T W F)^{-1} F^T W \triangle y^c
$$

(35)

After obtaining $\triangle x$, the current estimates are redefined as

$$
x^c = \triangle x + x^c
$$

(36)

Now using the current estimates, $F$, $W$, and $\triangle y^c$ are calculated. Then, $\triangle x$ estimate for the next iteration is calculated from (35) and this process is repeated until $\triangle x$ converges to a prescribed small value. A schematic representation of the Gauss-Newton algorithm is presented in figure 3.

VI. RESULTS

This section presents numerical simulations to assess the localization improvement due to the proposed fusion algorithm. Here we consider two separate simulation scenarios, for both scenarios, we assume that there are five sensor nodes located at

$$
S = \begin{bmatrix}
127 & 20 & 90 & 136 & 182 \\
107 & 22 & 0 & 68 & 59
\end{bmatrix}
$$

For simulation purposes, we assume a constant velocity model for the bullet. Thus, the Mach number is selected to be $m = 2$ and the speed of sound is selected to be $c = 342 m/sec$. For both scenarios, the measurement noise models are selected as $\sigma_{x_i} = \sigma_{y_i} = 5m$, $\sigma_{\omega} = \sigma_{\phi} = 4^\circ$, and $\sigma_{r} = 1 msec$. Since there exist several approaches to solve the nonlinear least-squares problem, two different methods are used to obtain solutions for both simulation scenarios. In the first method, the optimization problem is solved using the Gauss-Newton method [12] presented in the previous section. The second approach uses the Nelder-Simplex algorithm [13], i.e., the fminsearch function in Matlab.

Figure 3. Gauss-Newton Algorithm.
A. Simulation I

For the first simulation, the shooter is assumed to be located at $T = [50 \ 50]^T$ and we select the bullet trajectory to be $\omega = 30^\circ$. Figure 4 shows the first simulation scenario. Due to the sensor locations, the second and the third sensors do not receive the shockwave.

In order to evaluate the system performance, a Monte Carlo simulation is conducted for both the Gauss-Newton method and the simplex algorithm. The mean shooter locations and the associated error ellipses obtained from the Monte Carlo simulations using the Gauss-Newton method are given in figure 5. A separate plot is not provided for the results obtained using the simplex algorithm since they are very similar to that obtained for the Gauss-Newton method. Figure 5 indicates that the sensor five performs the worst out of the three sensors in the shockwave FOV. Figure 5 also indicates that the fused estimate is superior to the individual sensor estimates, and the uncertainty associated with the fused estimates is much less than the uncertainty associated with the individual sensor estimates.

Table I contains the mean shooter location estimate of the individual sensors and the fusion algorithms over the Monte Carlo run. The “average” estimate presented in table I indicates the estimate obtained by simply averaging the individual target estimate from sensors one, four, and five. Table I also contains the root mean square error (RMSE) associated with each estimate. Based on the RMSE presented in table I, one could conclude that that fused estimates outperform the individual sensors and the simple average estimate.

B. Simulation II

For the second simulation, the shooter is assumed to be located at $T = [150 \ -50]^T$ and we select the bullet...
trajectory to be $\omega = 170^\circ$. Figure 8 shows scenario for the second simulation. As shown in figure 8, only the second and the third sensors are in the FOV of the shockwave.

The mean shooter locations and the associated error ellipses obtained from the Monte Carlo simulation using the Gauss-Newton method are given in figure 9. Figure 9 indicates that both sensor two and sensor three are of similar accuracy since they are equal distance from the bullet trajectory. Figure 9 also indicates that the fused estimate is superior to individual sensor estimates and the uncertainty associated with the fused estimates is much less than the uncertainty associated with the individual sensor estimates.

Figure 10 presents the shooter localization error histogram for the average estimate and figure 11 presents the localization error histogram for the fused estimate obtained for the Gauss-Newton method.

Table IV contains the mean Results from Monte Carlo Runs

Table V contains the mean bullet trajectory angle estimate and associated RMSE obtained from the individual sensors and the fusion algorithms over the Monte Carlo runs. Finally, table VI contains RMSE associated with the sensor location estimates for simulation two. Note that the fusion algorithm was able to improve the sensor location accuracy by reducing the GPS uncertainties. The RMSE presented in tables IV, V, and VI, indicate that fused estimates outperform the individual sensors for the second simulation.
The shooter localization problem using a network of soldier-worn gunfire detection systems is considered here. This paper presents a fusion algorithm that utilizes the benefits of the sensor network layout of all the sensors within a small combat unit to help refine the shooter localization accuracy. The individual gunfire detection systems considered here are composed of a passive array of microphones that is able to localize a gunfire event by measuring the direction of arrival for both the muzzle blast and the shockwave. After detecting a gunfire, the individual sensors report their solution along with their GPS positions to a central fusion node. At the central node, the individual solutions are fused along with the GPS locations on the soldiers to yield a highly accurate georectified solution. Numerical results given here indicate that the fused estimates are more accurate than the individual localization results. Future work include further analyzing the linearization issues associated with the maximum likelihood approach and developing a mathematically rigorous method to quantify the uncertainties associated with the maximum likelihood estimates.
