ABSTRACT
This work shows a new method for blind separation of sources, based on geometrical considerations concerning the observation space. This new method is applied to a mixture of several sources and it obtains the estimated coefficients of the unknown mixture matrix A and separates the unknown sources. The principles of the new method and a description of the algorithm followed by some speed enhancements are shown. Finally, we illustrate with simulations of several source distributions how the algorithm performs.

1. INTRODUCTION
The separation of independent source signals from mixed observed data is a fundamental and challenging signal processing problem. In many practical situations, one or more desired signals need to be recovered blindly knowing only the observed sensor signals. When p different source signals propagating through a real medium have to be captured by sensors, these sensors are sensitive to all sources $s_i(t)$ and thus the signal $x_k(t)$, observed at the output of sensor $k$, is a mixture of source signals. With a linear and stationary mixing medium the sensor signals can be described by:

$$\mathbf{x}(t) = A \mathbf{s}(t)$$

where $\mathbf{x}(t) = (x_1(t), ..., x_p(t))^T$ is an experimentally observable $(n \times 1)$-sensor signal vector $s(t)$, with $\mathbf{s}(t) = (s_1(t), ..., s_p(t))^T$ is a $(p \times 1)$-unknown source signal vector having stochastic independent and zero-mean non-Gaussian elements $s_i(t)$, and $A$ is a $(n \times p)$ unknown full-rank and non-singular mixing matrix. The solution of the blind signal separation (BSS) problem consists of retrieving the unknown sources $s_i(t)$ from just the observations. To achieve this it is necessary to apply the hypotheses that the sources $s_i(t)$ and the mixture matrix $A = (a_{11}, ..., a_{pn})^T$ are unknown, that the number $n$ of sensors is at least equal to the number $p$ of sources, i.e. $n \geq p$, and that the components of the source vector are statistically independent yielding:

$$p(\mathbf{s}) = \sum_{i=1}^{p} p(s_i)$$

In order to solve the BSS problem a separating matrix $W$ is computed whose output is an estimate of the vector $\tilde{s}(t)$ of the source signals (Figure 1) such that:

$$\mathbf{y}(t) = W \tilde{\mathbf{x}}(t)$$

Any BSS algorithm can only obtain $W$ subject to:

$$W^{-1}A = DP$$

with a diagonal scaling matrix $D$ modified by a permutation matrix $P$. Recently, blind source separation (BSS) and Independent Component Analysis (ICA) have received much attention because of its potential applications in signal processing. A great diversity of estimation methods have been proposed based on some kind of statistical analysis, neural networks [7], the entropy concept [3], the geometric structure of the signal spaces [1,6,9], the fixed-point algorithm FastICA [5], the maximum likelihood stochastic gradient algorithm [2], the Jade algorithm [4], among others. Several geometric procedures have been used to separate either multivalued or analog signals, by analyzing the observed sensor signals in the resulting p-dim space of observations. In the following we will present a new geometric ICA algorithm which is based on rough density estimation.

2. PRINCIPLES OF THE NEW METHOD.
For $p = 2$ and with bounded values (uniform distribution), the observed signals $(x_1(t), x_2(t))$ form a parallelogram in
the \((\bar{x}_i, \bar{x}_j)\) space, as shown in Figure 1. We have demonstrated [8] that, through a matrix transformation, the coefficients of the matrix coincide with the slopes of the parallelogram. It can be seen that for random uniform sources, the parallelogram representing the space of observations \((\bar{x}_i, \bar{x}_j)\) is geometrically bounded within the segments between the points \(P_i\) to \(P_j\). The slopes of these segments give the coefficients of the estimated mixture matrix \(W^{-1}\). In order to obtain these segments, it is necessary to estimate the coordinates of those points \(P_i\), \(i=1...4\). Assuming non-uniformly distributed signal as the sources, for example speech signals with an underlying super-Gaussian distribution; the form of the sensor signal distribution in the space of observations is highly nonuniform too, as can be seen in Figure 5. In this case it is not sufficient to estimate the borders of the bounded space of observations. Rather, it is necessary to detect the directions of high density in the space of observations.

2.1. Description of the algorithm.

First of all, the algorithm computes the kurtosis of each component of the sensor signals and also the correlation coefficients between all observations. This is to detect whether the underlying source signal distributions correspond to sub- or super-Gaussian distributions. According to the Central Limit Theorem, mixtures will tend to be closer to Gaussian than the original ones. Consequently, kurtoses of the mixtures will be closer to zero (Gaussian distribution) than the sources:

\[
|\text{Kurt}(x_i)| \leq \max \left\{ |\text{Kurt}(s_j)| \right\} \quad i, j \in [1,...,N]
\]

In any case, for mixtures of two signals, they will tend to preserve the sub- or super-Gaussian nature of the original signals, assuming that both sources have the same sign in the kurtosis. If the kurtoses of all sensor components are positive, the algorithm searches for high density regions of the sensor signal distribution. With sub-Gaussian signals, the algorithm estimates the bounding box of the parallelogram representing the space of observations. The algorithm subdivides the space of observations \((\bar{x}_i, \bar{x}_j)\) into a regular lattice of cells with \(N\)-rows and \(M\)-columns (lattice of \(N\) by \(M\)) as shown in Figure 2. Then, the algorithm computes the number of cells in the lattice in which the number of points inside it is greater than a given threshold \(T\).

The distribution of sensor signals within each of these cells then is replaced by a prototype sensor signal vector. The prototype vector mostly does not point towards the centre of the cell because its position is weighted by the density of points \((x_{ij}, x_{ij})\) in this cell. This step greatly reduces the complexity of the algorithm, because the greatest number of points that the procedure needs to compute is \(N\times M\) (if the space of observations contains \(10^5\) points \((x_i, x_j)\) and \(N=M=20\) then the procedure only requires \(N\times M = 400\) points. To further reduce the number of points, the next step of the algorithm finds those points which either form the border of the hyperparallelepiped or mark the high density regions of the sensor signal distribution in the space, by looking for cells that have an empty neighborhood (such cells have fewer points than the threshold \(T\)). Then these cells without a complete neighborhood form the border of the distribution encompassing \(N\times R\) data points in the space of observations. The algorithm then computes the coordinates of \(P_1 = (p_{11}, p_{12})\) and \(P_2 = (p_{21}, p_{22})\). The space of observations has been reduced to \(N\times R\) data points which, in two dimensions, represent pairs of coordinates \((x_{ij}, x_{ij})\).

In this reduced set of \(N\times R\) data points, there exist data points \(P_1\) and \(P_2\) with largest Euclidean distance between them in the space of observations:

\[
d(P_1, P_2) = \max_{j, k \in [1, \ldots, NR]} d(P_1, P_{kj})
\]

Fig. 1. Space of observations: Representative points and straight lines.

Fig. 2 - Lattice of the space of observations in cells
Once points $P_1$ and $P_2$ have been identified, the algorithm calculates the equation of the straight line $R_1$ which passes through these points $P_1$ and $P_2$:

$$\begin{pmatrix} a_{11} \\ a_{22} \end{pmatrix}^{-1} = \frac{P_{12} - P_{11}}{P_{11} - P_{12}} : \begin{pmatrix} a_{11} \\ a_{22} \end{pmatrix} = \frac{P_{22} - P_{21}}{P_{21} - P_{22}}$$  \hspace{1cm} (8)

Once points $P_1$ and $P_2$ have been identified, the algorithm calculates the equation of the straight line $R_1$:

$$A = (p_{12} - p_{11}), \quad B = (p_{21} - p_{12}), \quad C = (p_{22} - p_{21})$$  \hspace{1cm} (7)

which passes through these points $P_1$ and $P_2$:

$$A x + B y + C = 0$$  \hspace{1cm} (6)

Using the coefficients of matrix $W$, the algorithm computes the inverse matrix $W^{-1}$ and reconstructs the unknown source signals $\hat{s}(t)$ (see Eq. (3)).

### 2.2. Further enhancements.

The computational order of the algorithm is polynomial:

$$\text{Comput Order} = (\text{DataPoints}^2 \cdot \text{XColumns} \cdot \text{YRows})$$  \hspace{1cm} (9)

As a further improvement, we propose the reduction of the number of points at the beginning of the algorithm with a random elimination through all the space of the joint distribution of the mixtures as long as enough data points are kept to correctly estimate the sources. A more elaborated proposal is eliminating those points of the joint distribution of the mixtures which lay within a calculated radius near the center of the joint distribution, because they are useless for the algorithm, due to its nature of computing contours using points whose Euclidean distances are the highest. From experimental results, we have derived equations (10) and (11) for the calculation of the radius based on the kurtosis and correlation of the mixture signals.

For sub-Gaussian mixtures, the algorithm will try to find the contour of the sensor signal distribution. In this case we determine the exclusion radius as follows:

$$R = \frac{\alpha}{\rho(x) + 0.1} \cdot \bar{\tau}$$  \hspace{1cm} (10)

where $\alpha$ is a constant (experimentally, a value of $\alpha=7.5$ was applied), $\rho(x)$ is the correlation of the mixtures and

$$\bar{\tau} = \sqrt{\frac{1}{N} \sum_{j=1}^{N} x(1,j)^2 + x(2,j)^2}$$

For super-Gaussian mixtures (positive kurtosis), the algorithm will search for high density regions of the joint distribution of the mixtures. Thus, the exclusion radius was calculated as:

$$R = 1.5 \cdot \bar{\tau}$$  \hspace{1cm} (11)

In figures 4 and 6, the effect of applying the exclusion radius to a mixture of two voice signals is shown. In this case, 79.2% lay within the exclusion radius and, therefore, they were removed.

### 3. Simulations and Results.

The new algorithm, firstly named as “LatticeICA”, has been tested on various ensembles of artificial sensor signals with an arbitrary number of samples drawn at random from sub- and super-Gaussian distributions like...
uniform, Gamma, Laplacian and Delta distributions, as well as with real world speech signals. To quantify the performance achieved we calculate both a crosstalking error of the original and recovered source signals as proposed by Amari et al. \[2\] as well as a component wise crosstalk measure and defined by:

\[ E(P) = \sum_{i=1}^{n} \sum_{j=1}^{n} \left[ \frac{|p_{ij}|}{\max(p_{ij})} - 1 \right] + \sum_{i=1}^{n} \sum_{j=1}^{n} \left[ \frac{|p_{ij}|}{\max(p_{ij})} - 1 \right] \] (12)

equal to the original and recovered source signals as proposed by Amari et al. \[2\] as well as a component wise crosstalk measure and defined by:

where \( P=(p_{ij}) = W \cdot A \).

The parameter \( \text{MSE} \) (Mean Square Error) measures the similarity of the signals \( s_i(t) \) and \( y_i(t) \).

3.1 Simulation 1: Uniform noise.

The original source signals are two uniform noises of 110.250 samples. As a representative example we first present a simulation where a lattice of 15 by 15 cells has been calculated within the algorithm to subdivide the space of observations into 225 cells, and threshold \( \text{TH} \) set to 175 samples within each cell. The original and estimated matrices are:

\[
A = \begin{bmatrix} 1 & 0.5 \\ 0.6 & 1 \end{bmatrix}; \quad W = \begin{bmatrix} 1 & 0.747 \\ 0.615 & 1 \end{bmatrix}\] (13)

The Amari performance index for this simulation is \( E(W \cdot A) = 0.0703 \). The crosstalk parameters were \( \text{Crosstalk1}(E_{s1}) = -53 \, \text{dB} \) and \( \text{Crosstalk2}(E_{s2}) = -29 \, \text{dB} \). In Figure 4 it is depicted how the algorithm finds the contour to give the independent components.

\[
E(P) = \sum_{i=1}^{n} \sum_{j=1}^{n} \left[ \frac{|p_{ij}|}{\max(p_{ij})} - 1 \right] + \sum_{i=1}^{n} \sum_{j=1}^{n} \left[ \frac{|p_{ij}|}{\max(p_{ij})} - 1 \right] (12)

3.2 Simulation 2: Speech signals.

Next, the algorithm separate two super-Gaussian signals with a Laplacian distribution and 10000 samples each. The lattice was automatically computed to be 16 rows and 16 columns, using \( \text{TH} = 10 \). The original and estimated matrices were:

The joint distribution of the mixtures points out the super-Gaussian nature of the sources (see Figure 5). The matrix performance index for this simulation was \( E(W \cdot A) = 1.2931 \), with \( \text{Crosstalk1}(E_{s1}) = -39 \, \text{dB} \) and \( \text{Crosstalk2}(E_{s2}) = -24 \, \text{dB} \). In figure 6 it is shown how the algorithm searches for the lines of higher density instead of the contour plot.

Fig. 5 – Joint distribution of two voice signals.

3.3 Simulation 3: Comparison with other algorithms.

In the third simulation we started a more systematic exploration of the algorithm and compared the results to those obtained with two other algorithms, the fastICA Hyvärinen and Oja) and Jade algorithms (Cardoso, 1999). We tried random mixture matrixes over uniform and

Fig. 6 – Performance of the LatticeICA algorithm for a two real voice signals mixture.

3 Simulation 3: Comparison with other algorithms.

In the third simulation we started a more systematic exploration of the algorithm and compared the results to those obtained with two other algorithms, the fastICA Hyvärinen and Oja) and Jade algorithms (Cardoso, 1999). We tried random mixture matrixes over uniform and
Laplacian mixtures of 10000 samples, running 100 simulations each time, with automatic parameters. With fastICA the number of bins has been choosen in all cases to be 180. The NRMS (normalized root mean squared error) in each case and the corresponding average convergence times (Pentium IV 1.5 GHz., 512 MB RAM, Matlab environment) are summarized in Table 1. Although, both FastICA and Jade algorithms globally get better results than LatticeICA in most of the simulations, LatticeICA shows a great performance especially for super-Gaussian mixtures and it outperforms previous geometric algorithms. As a particular advantage of LatticeICA when compared with FastICA and Jade it remains its easy hardware implementation, due to the fact that it only computes simple arithmetic operations. Future enhancements in fine tuning the radius exclusion and adjusting the final separation lines will certainly lead to a better performance.

Table 1. Comparison of performance of the new algorithm (shortly named LatticeICA) with FastICA and Jade.

3.4 Simulation 4: Extension to higher dimensionality.

Finally, we show how this algorithm can be extended to higher dimensionality situations by attempting to separate the projections of \( p \) mixed signals from \( \mathbb{R}^p \) onto \( \mathbb{R}^2 \). The signals are shown in figures 7 to 9 (with a Laplacian noise, a music source and a speech signal). The original and obtained matrices are:

\[
A = \begin{bmatrix}
1 & 0.5 & 0.5 \\
0.5 & 1 & 0.5 \\
0.5 & 0.5 & 1
\end{bmatrix} \quad W = \begin{bmatrix}
1 & 0.64 & 0.73 \\
0.45 & 1 & 0.63 \\
0.46 & 0.47 & 1
\end{bmatrix}
\] (15)

In Figure 8 can be seen the 3-dimensional mixture and the projections in each of the planes which will be the inputs to the algorithm. Figure 9 depicts the separated signals of the proposed LatticeICA algorithm employing radius exclusion and random elimination of points.
Finally, Table 2 shows details about the signals properties, algorithm parameters and simulation results with and without the enhancements proposed. MSE stands for the Mean-Squared of Errors, “Cross” stands for the crosstalk, “Thresh” is the threshold and “Samp” is the number of samples.

4. CONCLUSIONS.

We have developed a new geometry-based method for blind separation of sources which greatly reduces the complexity and computational load inherent in the standard geometric ICA algorithms. This new algorithm is based on a tessellation of the input space where in each cell a code book vector is determined to represent the center of gravity of the local distribution of sample vectors. Depending on the type of distribution, either sub- or super-Gaussian, the slopes of the border lines or the diagonals are determined to obtain the coefficients of the estimated mixing matrix \(W\). The method lends itself for an easy hardware implementation and is also very intuitive in terms of computer applications. Furthermore, this method could be used to detect the perimeter or outlines in simple two-dimensional figures. In the future we will intend to implement this method for more than two signals without using projections but working in the p-dimensional space.
